Re-examining the impact of climate change on global livestock production

Abstract

Attempts to analyze the effect of weather shocks on livestock production have 5 been carried out using integrated assessment models (IAMs) or the cross-sectional 6 (Ricardian) method. However, these methodologies are fraught with obvious shortcomings, such as omitted variable bias, amongst others. This paper, therefore, 8 re-examines the relationship between climate change and global livestock produc-9 tion using an established econometric strategy that takes care of the pitfalls inherent 10 in the conventional approaches. Using country-level data and a variety of specifica-11 tions, we find that a 1°C increase in temperature will lead to a 9.7% reduction in 12 global beef production on average. These adverse effects are amplified in hot, poor, 13 and agriculture-dependent countries. Besides, we find that a marginal increase in 14 annual precipitation would lead to a 2.1% increase in beef production in tropical 15 countries but a 1.9% decrease in temperate ones. Also, our forecasts show that 16 climate change will reduce animal output by a further 20% in the mid-century and 17 an additional 40% by the end of the century assuming no adaptation other than the 18 degree of adaptation observed in the historical period. 19

²¹ 1 Introduction

The rate of increase in earth's average surface temperature in the last 30 to 40 years 22 has far outstripped that of any other period for the last 20,000 years (IPCC 2018). Many 23 climatologists forecast a further rise in global temperature in the near future (Allen et al. 24 2014, IPCC 2018). Similarly, rainfall patterns have become more erratic and unpre-25 dictable (Roudier et al. 2011, Lobell et al. 2013, Lobell & Asseng 2017). These weather 26 fluctuations and and the associated extreme events have been evidenced in previous stud-27 ies as major influencers of agricultural production (Aragón et al. 2021, Chen & Gong 28 2021), economic growth (Kalkuhl & Wenz 2020, Smith & Ubilava 2017, Dell et al. 2012), 29 mortality (Emediegwu 2021, Barreca 2012, Deschênes & Greenstone 2011), and conflict 30 (Harari & Ferrara 2018, Hsiang et al. 2013, 2011). The agricultural sector bears the 31

largest economic impact of changing climate because of the size, significance, and sensitivity of the sector, especially in rural communities situated in low latitudes (Mendelsohn
2008).

Agriculture is of global importance as it employs more than 70% of the world pop-35 ulation, with more concentration on the rural poor in developing regions (International 36 Labour Office 2017). The sector also accounts for 4 percent of global gross domestic 37 product (GDP) and more than 25% of GDP in some developing countries (WDI 2017). 38 In addition, OECD/FAO (2016) documents that livestock production currently accounts 39 for some 40 percent of the gross value of agricultural production. This share is more 40 than 50 percent in some industrial countries and about 33 percent in most developing 41 countries. Further, livestock is often kept as a form of wealth and food "buffer" stock 42 in the event of crop failures, thus forming an important part of consumption smoothing 43 behavior. 44

Besides the fact that more than half of the world's land surface is used for grazing 45 livestock or growing crops for animal feeds (FAOSTAT 2018), the importance of livestock 46 production can also be viewed within the lenses of global animal consumption. FAOSTAT 47 (2018) documents the annual, global meat consumption between 1988 and 2018 to be 48 around 350 million tonnes, with the expectation that consumption could reach up to 49 570 million tonnes by 2050. The expected remarkable increase in meat demand has 50 been associated with population and income growth, as well as lifestyle and dietary 51 habits changes (FAO 2018). More importantly, to meet global meat consumption by 52 2050 would require a doubling of meat production from the 2008 level (FAOSTAT 2018). 53 Consequently, given the importance of livestock production in the global economy and 54 the reality of a changing climate, detailed attention needs to be paid to the relationship 55 between the duo. 56

There have been attempts to quantify the damage estimate of climate change on 57 livestock production using integrated assessment models. This approach uses biophysical 58 livestock simulation models in conjunction with economic models to estimate animals' 59 responsiveness to climate change (see, St-Pierre et al. 2003, Rötter & Van de Geijn 1999, 60 Klinedinst et al. 1993, Johnston 1958, for empirical examples). The attractiveness of 61 the agroeconomic approach is based on the deep comprehension of animal science (Antle 62 & Stöckle 2017). However, a major weakness pointed out by Chimonyo et al. (2015) is 63 that most biophysical simulation models are tailored towards mono cultural practices, 64 making them impracticable for multi-livestock analyses. Additionally, these models have 65 been daubed as the *dumb-farmer* scenarios because they omit the possibility of farmer's 66 adaptive response such as livestock switching and changes in acreage, hence providing an 67 exaggerated estimate of climate change impact on livestock production. Other deficiencies 68 associated with process-based models are the limited number of animal models available 69 and the problem of external validity, given that models need to be carefully calibrated to 70

⁷¹ reflect local conditions (Mendelsohn & Dinar 2009).

An alternative approach to improve on the shortcomings of the IAMs is the cross-72 sectional (or Ricardian) approach introduced in Mendelsohn et al. $(1994)^1$, and applied 73 in several studies (Feng et al. 2021, Taruvinga et al. 2013, Kabubo-Mariara 2009, Seo & 74 Mendelsohn 2008).² This approach, which introduces the revealed preference technique in 75 estimating the impact of climate change on agriculture, exploits cross-sectional variation 76 across spatial units (households, counties, countries, etc.) to evaluate the effect of long-77 run climate on average livestock values. Despite the attractiveness of the Ricardian model 78 because of its ability to capture long-run farmer's adaption, it severely suffers from the 79 problem of omitted variables bias.³ The omission of relevant variables (e.g., closeness to 80 river source) that are correlated with both climatic factors and the dependent variable 81 (e.g., farmland value) can bias climate impact estimates. Dell et al. (2014) also submit 82 that even in the absence of omitted variable bias, it is unlikely to obtain a true estimate 83 of how climate change will impact agricultural activities in the long run (e.g., next 50 84 or 100 years) because the historical equilibrium the cross-section represents may depend 85 on mechanisms that act differently. These limitations are addressed in fixed effect panel 86 data models. 87

Unlike the Ricardian model, panel data analysis uses group fixed effect (FE) to ac-88 count for omitted variables that correlate with climatic and response variables (Blanc 89 & Schlenker 2017). Panel data models exploit the exogeneity of cross-time variations in 90 weather to identify the causal effects of weather variables, such as temperature and pre-91 cipitation, on several economic outcomes, including agricultural output. This established 92 econometric approach has been popularly used in the climate econometrics literature to 93 estimate the impact of climate change on several economic outcomes.⁴ Despite these 94 interesting works, rigorous empirical work on the impact of climate change on global 95 livestock production is lacking. Such work would help understand the effect of climate 96 at a global rather than a local level, as exemplified in previous studies that employed 97 integrated assessment models or cross-sectional analysis. 98

99

This paper intends to research in this direction by using a panel of national livestock

¹This approach was originally applied to crop production but has been applied extensively to analyze climate change impacts on livestock production.

²The method follows Ricardo's observation that the present value of future net productivity is reflected by land rents (Ricardo 1817, 1822). This, as argued by Mendelsohn & Massetti (2017), suggests that land productivity, rent, and net revenue are equivalent regardless of the type or number of crops or livestock grown in the farm, and what technology is applied since farmland value is the present value of the stream of future rents.

³Other shortcomings include the assumption of constant prices and non-measurement of adjustment costs from one equilibrium to another, as well as the inability to disaggregate the results into crop- or livestock-specific impacts (Cline 1996, Darwin 1999, Carter et al. 2018).

⁴Some previous climate-related studies that employed the panel data analysis include Kalkuhl & Wenz (2020), Dell et al. (2012) (economic growth); Harari & Ferrara (2018), Hsiang et al. (2013) (conflict); Hsiang & Meng (2015), Deschênes & Greenstone (2007) (agriculture); Emediegwu (2021), Barreca (2012), Deschênes & Greenstone (2011) (mortality).

production and local weather fluctuations from 187 countries. Empirically, we address some specific shortcomings in previous literature with respect to methodology, data, temporal and spatial scale. The methodology accounts for omitted variable bias; the spatial and temporal dimension of our dataset allows for substantial variation through which we can identify the effects of short-term weather shocks on livestock production.

Our results show a robust negative effect of temperature changes on global livestock production and a positive impact of rainfall fluctuations. We offer further evidence that the effect of temperature is more concentrated in hot, poor, and agricultural-dependent countries. Also, we find that climate change will reduce animal output by a further 20% in the mid-century and an additional 40% by the end of the century. Also, while rainfall benefits in the tropical regions moderate these temperature-caused adverse effects, they are further aggravated by rainfall in the temperate regions.

Notwithstanding the intuition from our results, it is important to note the following 112 caveats. Our methodology does not account for adaptation. In the face of climate change, 113 it is impossible to rule out the possibility of farmers taking adaptive measures (such 114 as migrating animals to cool areas) to alleviate the adverse effects of climate change. 115 Accounting for adaptation or mitigation measures would attenuate the damage estimate 116 from our model.⁵ Also, we do not account for inter-seasonal changes in weather, which 117 could also amplify the adverse effect of climate change. Given these two important 118 caveats, our results should be seen as *middle-of-the-road* estimates. Notwithstanding the 119 caveats, our work is very informative and complements the growing literature that seeks 120 to understand how climate change affects livestock production. 121

The remainder of the paper is adumbrated as follows. The next Section provides several channels through which climate change can impact livestock production. We describe the data and methodology in Section 3, while the various results are discussed in Section 4. Section 5 deals with climatic projections and predicted impacts. The paper ends with some concluding remarks in Section 6.

¹²⁷ 2 Climate change and livestock production: potential ¹²⁸ channels and mechanisms

In their fifth assessment report, the Intergovernmental Panel on Climate Change (IPCC) predicted that global surface temperatures would increase by 0.3°C to 4.8°C by the end of the century (IPCC 2018). Using NASA data, Hansen et al. (2010) show

⁵Auffhammer & Schlenker (2014) attenuate this claim by suggesting that the introduction of nonlinear weather measures introduces cross-sectional variation in climate, hence the estimated parameters, at least, partially captures long-run adaptation. However, the extent to which the adaptation effect is captured is still a subject for debate as it depends on the size of the cross-sectional variation *vis-a-vis* location-specific weather variation (see, Carter et al. (2018) for more intuition).

that earth's average global temperature has grown by over 1°C since 1880, and two-thirds
of this warming occurred since 1975, at a rate of roughly 0.15-0.20°C every decade. These
changes in climatic patterns could affect livestock in several ways, directly or indirectly.

¹³⁵ Climate change affects livestock directly by altering their reproduction processes, feed ¹³⁶ conversion ratio⁶, and health via the emergence of new diseases (and the increase in the ¹³⁷ spread of existing ones). For example, Barati et al. (2008) show that heat stress can ¹³⁸ influence animals' oocyte growth, as well as their pregnancy rate and embryo develop-¹³⁹ ment. Besides, as temperature increases, the activity of pathogens and parasites increase, ¹⁴⁰ vector-borne diseases spread faster and host resistance is diminished (Thornton et al. ¹⁴¹ 2015).

On the other hand, the indirect effects include climate impacts on the availability of water, the access to and quality of feed, as well as the likelihood of morbidity when disease does occur (Rojas-Downing et al. 2017, Walthall et al. 2012). Rojas-Downing et al. (2017), Nardone et al. (2010), for example, detail how climate change could affect livestock health directly by increasing potential morbidity and death and indirectly by the increasing disease factors.

Agricultural activity is the largest consumer of water resources with around 70% of 148 use (Thornton et al. 2015), and the demand for even more sustainable water sources 149 for agricultural purposes is increasing due to the combination of droughts, water bodies 150 depletion, and increasing human population. More so, livestock needs water because of 151 its vital role in the sustenance of life and other biological processes like fertility and milk 152 production. For example, cows can stay up to seven days without drinking water in 153 cool climates: however, they would require water every six hours to survive under high 154 temperatures (Nardone et al. 2010). As temperature rises, the lack of sufficient water 155 could cause more migration in search of water by nomadic cattle herders, leading to an 156 increase in communal clashes and violence in developing countries (Döring 2020, Freeman 157 2017). These migratory activities and conflicts increase animals' feed conversion ratio, 158 thereby reducing their production efficiency. 159

When precipitation departs from predictable patterns, agricultural activities, espe-160 cially in developing countries where most crop production is rain-fed, also suffer. Besides, 161 the composition of pastures will also be affected due to plant competition for water in 162 drought seasons and leaching of soil nutrients during flooding (Thornton et al. 2015). 163 In addition to the ability of the crops to grow, the quality of the forage could also be 164 affected by changes in environmental conditions. For example, flooding could change 165 the root structure, thereby reducing total yield and nutrient quality (Polley et al. 2013, 166 Baruch & Mérida 1995). Consequently, these alterations in the quantity and quality of 167

⁶Feed conversion ratio (FCR) is one of the methods for measuring livestock production efficiency. It is defined as the weight of feed intake divided by the animal's weight gain. Higher FCR values correspond to lower production efficiency. Typically, beef has higher FCR (6.0–10.0) than most livestock including pigs (2.7 - 5.0), chicken (1.8 - 2.0) and farmed fish and shrimp (1.0 - 2.4) (Fry et al. 2018).

animal feed by meteorological factors influence the growth and development of livestock.
To sum up this section, there are several channels through which annual weather
shocks can influence livestock production: however, our intention is not to quantitatively determine the individual contributions of each channel, rather we are employing a
reduced-form framework to analyse the general pass-through effect of weather fluctuation
on global livestock production.

¹⁷⁴ 3 Data and Summary Statistics

¹⁷⁵ 3.1 Data Sources and Description

Animal Data. We draw country-level cattle average production (tonnes) from the 176 FAOSTAT database.⁷ We use cattle, generically to include the production of both beef 177 and buffalo meat. The Food and Agriculture Organization (FAO) obtained these figures 178 from various sources: governments through national publications and FAO questionnaires 179 (both paper and electronic); unofficial sources; national and international agencies or 180 organizations. Here, we focus on cattle for two main reasons. Beef is one of the most 181 consumed forms of animal protein in most parts of the world, coming behind pork and 182 poultry (FAO 2018).⁸ Two, aside from meat, cattle are reared for their various by-183 products such as dairy products, manure, hides for making leather, riding or drafting for 184 pulling carts, and other farm implements. These value-added products raise the economic 185 importance of cattle. Our sample covers 157 countries with at least 25 years of cattle 186 production data, while we consider other sub-sample for robustness analysis. 187

Weather Data. Our historical weather dataset is obtained from the University of 188 Delaware Terrestrial Air Temperature and Precipitation: 1900 - 2017 Gridded Monthly 189 Time Series. V4.01. This dataset provides global gridded high resolution station (land) 190 time series data for mean air temperature and total precipitation at 0.5° resolution (ap-191 prox. 56 km \times 56 km across the equator).⁹ We aggregate the weather data to country-year 192 level by overlaying a world polygon with country boundaries on the average temperature 193 and total precipitation for each grid cell and then taking a weighted average across all grid 194 cells per country. We use cattle population-weighted weather average to account for het-195 erogeneity in cattle population within and across countries. Our cattle population weights 196 are from 2010 population count at 5 minutes of arc (~1 km at the equator) resolution 197 extracted from FAO Gridded Livestock of the World (GLW v3) database (Gilbert et al. 198 2018). We also present results using alternative weather dataset and several weighting 199 measures in Tables 6 and 7 of the Appendix, respectively. 200

⁷The cattle data is accessible *via* http://www.fao.org/faostat/en/#data/QL

 $^{^{8}\}mathrm{It}$ is recognized that this varies between country and within age-group and depends on cultural preferences and religious beliefs.

⁹See Willmott & Matsuura (2019) for a complete description of the dataset.

Climate Change Prediction Data. We rely on the Australian Community Climate 201 and Earth System Simulator (ACCESS-ESM1.5) of the Commonwealth Scientific and In-202 dustrial Research Organisation (CSIRO) for our climate change projection data.¹⁰ This 203 general circulation model (GCM), which belongs to the sixth phase of the Coupled Model 204 Intercomparison Project (CMIP6), is made up of atmospheric and land components com-205 piled as a single executable, coupled to ocean and sea-ice executables.¹¹ We use the 206 middle-of-the-road scenario (SSP3-7.0) of the model to construct country-year panel for 207 average temperature and total precipitation from 1970 to 2100.¹² We use our projected 208 data to examine medium-term (average over 2041 - 2060) and long-term (average over 209 2081 - 2100) impacts of climate on cattle production. 210

211 3.2 Summary Statistics

We report the summary statistics of our variables at country-level in Table 1. Most 212 of the countries in our sample have data from 1961 to 2017, with few beginning in later 213 years; hence our panel is unbalanced.¹³ Panel A describes the historical dataset, whereas 214 Panels B and C summarize the climate change projection data in the mid-future and by 215 the end of the century, respectively. Over the period under consideration, the average 216 global temperature is about 20°C. Europe and Central Asia (ECA) is the coldest region (-217 7.43°C), while Sub-Saharan Africa (SSA) has the highest average temperature (30.09°C) 218 and the least variation in temperature. At the same time, East Asia and Pacific (EAP) has 219 more varied temperature range, followed by North America. In terms of rainfall, South 220 Asia experienced more rainfall and more variation in rainfall than other regions over the 221 sample period, while Middle East and North Africa (MENA) has the lowest rainfall. In 222 terms of beef production, every region exceeded the world's average production, except 223 MENA and SSA, regions with the least rainfall and the highest temperature, respectively. 224 In terms of spatial distribution of average measures, Figure 2 in the Appendix shows that 225 regions in the south pole are hotter on average than their counterparts in the north pole, 226 while there is variation in the distribution of rainfall across regions and countries. The 227 production of cattle appears to be significantly less Africa (SSA and part of MENA) than 228 in other parts of the world. 229

 $^{^{10}\}mathrm{This}$ data is hereafter referred to as ACCESS.

¹¹In lieu of presenting detailed description of the simulation processes of these global climate models (GCMs), readers are referred to Eyring et al. (2016), whereas the dataset can be retrieved from the CMIP6 website https://pcmdi.llnl.gov/?cmip6.

¹²SSP3-7.0 is a new shared socioeconomic pathway added to CMIP6 that lies between the worst case (SSP5-8.5) and a more optimistic (SSP4-6.0) scenarios.

¹³Those countries with data beginning later than 1961 are mostly due to the timing of their independence. For example, many countries like North Macedonia, Ukraine, *etc.*, became independent after the collapse of the Soviet Union in 1991, hence their data starts from 1992

Note: SD denotes standard deviation. The weather and climate entries are cattle population adjusted. Figures in bracket are percentage changes from historical figures.

Panel B shows the summary of the ACESSS ssp3.70 predicted changes in climate in 230 the mid-future (2041 - 2060) across regions of the world. The model predicts a 2.2°C 231 rise in global temperature with North America and MENA as the leading regions to 232 experience more warming. The Panel also shows that while other regions will benefit 233 from a positive change in rainfall, Latin America and Caribbean (LAC) will experience 234 a fall in total rainfall. Panel C summarizes the predicted state of climate by the end 235 of the century (2061 - 2100). Based on this model, more global warming is predicted, 236 doubling the mid-future change. North America and ECA are predicted to have the 237 highest temperature rise. In addition, LAC and EAP will experience reduction in total 238 rainfall by the end of the century. Figures 3 and 4 in the Appendix show the spatial 239

variation of the predicted climate change in the mid-future and by the end of the century,respectively.

²⁴² 3.3 Econometric Strategy

In this sub-section, we construct a panel data model at country/year level to analyze the impact of climate change on production. Our model takes the reduced form:

$$y_{ct} = \alpha_c + \gamma_r t + T_{ct}\beta_0 + P_{ct}\beta_1 + \epsilon_{ct} \tag{1}$$

where y_{ct} is log of beef production (in tonnes) in country c and year t, α_c are country 245 fixed effects to control for country-specific time-invariant factors of beef production, γ_r 246 are region-specific trends which accounts for time-changing determinants of mortality 247 that are common within a region, and ϵ_{ct} are idiosyncratic errors. We control for possible 248 spatial and serial correlation in the standard error terms ϵ_{it} using the approach described 249 in Hsiang (2010) and an arbitrary distance of 1000 km and time lag of 3 years.¹⁴ In 250 keeping with the conventional checks, we report results with varied cutoffs and alternative 251 standard error corrections in the Tables 8 and ?? in the Appendix, respectively. 252

Our main covariates, T_{ct} and P_{ct} , are matrices of annual average temperature (in °C) 253 and yearly total precipitation (in mm/year), respectively, in country c and year t. These 254 climate variables of interest also include their squared terms to capture non-linearities 255 (Dell et al. 2014). We do not include other controls for the following reasons. First, 256 important physical factors such as elevation are fixed over time and cannot be distin-257 guished from country-specific effects. Hsiang (2016), Dell et al. (2014) further argue that 258 the addition of more controls will not necessarily move the climate change impact esti-259 mate closer to its true value if the controls (such as GDP and institutional measures) 260 are outcomes of climate. Rather, such addition will induce an "over-controlling problem". 261 Consequently, the standard practice in climate change applied studies using panel data 262 is to exclude other time-varying controls.¹⁵ Furthermore, we understand that some mea-263 surement errors may occur either in the quantity of beef production reported by countries 264 or in the imputation by FAO for non-reporting countries. However, we believe that these 265 errors are exogenous to our explanatory variables, hence such errors might only result in 266 imprecise rather than biased estimates. 267

In subsequent analysis, we estimate equation (1) for several countries' characteristics separately. While we do not claim strict causality in this study as it is difficult to do so with any observational study, this paper is careful to address certain empirical is-

 $^{^{14}}$ Hsiang (2010) correction technique is a panel data extension of Conley (1999) correction for cross-sectional data.

¹⁵This conventional practice is evidenced in empirical studies like Hsiang & Meng (2015), Schlenker & Lobell (2010) (agricultural production); Emediegwu (2021), Deschênes & Greenstone (2011) (mortality); Kalkuhl & Wenz (2020), Dell et al. (2012) (economic growth), and Hsiang et al. (2013, 2011) (conflict).

sues. First, we use country-specific fixed effects to account for time-invariant prevailing 271 conditions in a country that may affect beef production. For example, hotter countries 272 generally experience lower harvest, which indirectly affects cattle production via avail-273 ability and pricing of grain (Walthall et al. 2012). Second, there is possibility of temporal 274 trends in both environmental factors and animal production in any region, with the latter 275 coming from certain dynamics of growth that are unrelated to the weather agents. To 276 mitigate the effect of such trends, we include region-specific trends which account for 277 time-changing determinants of beef production that are common within a region. 278

The controls put in place in the model allow us to estimate the effect of a quasi-random weather variation on animal production. We further expose the models to sensitivity checks to ascertain the robustness of our result.

²⁸² 4 Empirical Results and Discussion

283 4.1 Main Results

The main results are presented in Table 2. The table, in addition to showing ag-284 gregate results, also displays the heterogeneous impact of weather variation on animal 285 production based on (i) whether a country is hot or cold for most part of the year (ii) in-286 come classification (iii) agricultural role. All estimates are reported with standard errors 287 adjusted for spatial (1000 km) and serial (3-years) correlation. On aggregate, Table 2 288 shows that temperature has a negative and statistically significant relationship with beef 289 production. Specifically, a 1°C increase in temperature will lead to a 9.7% reduction in 290 beef production. However, an in-depth look at a more disaggregated level reveals that the 291 impact of temperature is higher in tropical regions than in temperate regions, implying 292 that the overall negative estimate is driven by weather happenings in certain regions of 293 the world. While a 1°C increase in temperature will result in about a 20% fall in cattle 294 production in tropical countries, there is no significant effect of such a rise in temperate 295 regions. We show in Appendix 10 that using a live animal indicator (cattle stock) as 296 outcome variable produces similar qualitative results.¹⁶ 297

On the other hand, the adverse effect of a marginal rise in temperature is evidenced in both rich and poor countries; however, the impact is stronger in the latter. We find that a 1°C increase in temperature will reduce animal production by 27% in poor countries and 4% in rich ones. Further, our results reveal that the severity of the impact of temperature on cattle production also depends on whether a country is agriculture-dependent or not. We find that the more agriculture-dependent a country is, the greater the impact of temperature changes. On average, the adverse effect of a 1°C increase in temperature

¹⁶Cattle stocks indicate the number of cattle and buffalo present in the country at the time of enumeration. It includes animals raised either for draft purposes or for meat.

Table

V country is defined as tropical if its median temperature is above the global median; otherwise, it is temperate. A country is rich iff it is higher income or upper-middle income by World Bank classification, else it is poor. A country is agriculture-dependent if it has above median share of GDP in agriculture in 2000. Temperature is in degrees Celsius and precipitation is in mm units per year. Sample period is **Significant at the 1 percent level. *Significant at the 5 percent level. *Significant at the 10 percent level.

is four times larger in agricultural economies than in non-agricultural ones. Our results
imply that beef production is most seriously at risk of global warming in hot, poor, and
agriculture-dependent countries. This dichotomy in the burden of impact is important in
explaining possible channels (e.g., how agriculture-intensive a country is) through which
weather changes affect beef production. We explore such potential channels in a later
subsection.

Going back to Table 2, we explain the effect of precipitation changes on beef produc-311 tion. On aggregate, precipitation has a positive but insignificant effect on beef production: 312 however, there are significant differences in results when heterogeneity is considered. For 313 example, while a marginal rise in precipitation is beneficial to beef production in tropical 314 countries, it is harmful in temperate economies. Specifically, where a 1 mm increase in an-315 nual precipitation would lead to a 2.1% increase in beef production in tropical countries, 316 a similar increase in precipitation is associated with a 1.9% decline in beef production in 317 temperate regions. Along national income lines, we find that rainfall changes have no sig-318 nificant effect on beef output rich countries but positively affect beef production in poor 319 countries. This result could follow from the fact that most poor countries are situated 320 in the tropics. This heterogeneous effect is also duplicated when considering whether a 321 country is agriculture-dependent or not. We find that an extra mm of annual precip-322 itation would generate a 3% improvement in beef production in agriculture-dependent 323 countries, with no significant effect in a non-agricultural country. Overall, we find that 324 the impacts of temperature changes are more severe in certain regions - hot, poor, and 325 agriculture-dependent countries, as shown in Figure 5 in the Appendix. However, the 326 positive effect of precipitation changes in these regions means that more rainfall will at-327 tenuate the negative impact of temperature rise on beef production. However, the extent 328 to which this would reduce the temperature impact is an empirical question. 329

The quadratic term of temperature is significant across all specifications, unlike precipitation, which indicates a potential nonlinear (convex by nature) relationship between temperature and beef production. Such nonlinearity means there is a minimally beneficial level from which the effects start rising, significantly or insignificantly, in both directions.

334 4.2 Robustness Results

In this section, we ascertain our results' (in)sensitivity through a series of robustness tests. Our robustness tests involve re-modeling equation (1) with different functional forms and panel samples.¹⁷ The results displayed in Table 3 entail aggregate estimates and estimates for heterogeneous parts that show significant impacts.

Lagged Weather Outcomes. We test whether our estimates are sensitive to the addition of weather lags. It is possible for variability in economic outcome, like livestock

¹⁷Results of further robustness tests can be found in the Appendix.

production, to be coming from past weather occurrences. Livestock production is a 341 multi-year process, which means that farmers decide what year to send animals to the 342 slaughter house to produce meat. Hence, the need to see to what extend past weather 343 occurrence influence current production levels. The first and second rows in Table 3 dis-344 play the results with lagged weather variables added to the baseline model. With the 345 inclusion of one-year temperature lag, the cumulative effects are broadly similar in terms 346 of significance and sign. However, there is an increase in the size of the estimates in the 347 heterogeneous components, but a reduction by half at aggregate level. This increase in 348 magnitude implies that the effect of lags is reinforcing rather than diminishing. On the 349 other hand, the effect of precipitation is qualitatively similar to the baseline estimates. 350 The addition of a one-year lagged precipitation measure increases the magnitude of the 351 cumulative impact of precipitation on beef production marginally, except at the aggregate 352 level, where the effect of precipitation becomes slightly significant.¹⁸ 353

Logged Weather Outcomes. We consider a log-log functional form where the weather 354 variables are log-transformed. The implication of this transformation is a large loss of 355 observations since the log of zero and negative temperatures is undefined. Row 3 in Table 356 3 reports the estimates from re-analyzing equation (1) using log of weather variables. 357 In terms of interpretation, the estimates report elasticity, which is qualitatively similar 358 to baseline estimates. Although in terms of magnitudes, the estimates here are lower 359 than the baseline's, which is unsurprising given the loss of observations following the 360 log-transformation. 361

Interaction Term. Further, we checked if our results are robust to the inclusion of an interaction term of temperature and precipitation. The results displayed in Row 4 show marginal estimates at sample mean of interaction between temperature and precipitation. The estimates are broadly consistent, except that the effect of precipitation becomes insignificant for tropical and agriculture-dependent groups.

Outliers Influence. We checked whether our estimates are driven by some outlier countries. We describe these countries as those with duplicate beef production entries in the original FAO dataset. Purging our sample of the 22 countries that fall under this category do not alter our results significantly.¹⁹ The results in Row 5 are analogous to the baseline results, confirming the stability of our baseline estimates.

Sub-Saharan Africa's (SSA) Influence. Next, we consider the influence of SSA on our results. SSA is an important region, given that most of the countries, as shown in Figure 5 in the Appendix, are hot, poor, and agriculture-dependent. First, we re-estimate equation (1) without inputs from SSA. Results from Row 6 are quite similar in sign, significance, and size to the main estimates. Following, we re-estimate the main equation with SSA

¹⁸We use one-lag as subsequent additions do not change the results significantly.

¹⁹The countries excluded are Afghanistan, Bahamas, Botswana, Comoros, Dominican Republic, Equatorial Guinea, Ghana, Guatemala, Guinea, Guinea-Bissau, Haiti, Iceland, Lesotho, Liberia, Mauritania, Mozambique, North Korea, Oman, Qatar, Sierra Leone, Syrian Arab Republic, Turkey

if its median temperature is above the global median, "poor" if it is classed as a lower income or lower-middle income by World Bank classification, "agriculture-dependent" if it has above median share of GDP in agriculture in 2000. **Significant at the 1 percent level. **Significant at the 1 percent level.

dataset only and found broadly analogous results, albeit with larger magnitudes than the
baseline estimates as shown in Row 7. Both results indicate that while the impact of
weather changes on SSA is huge, excluding the region does not cancel the general trend.
Hence, our results are robust to the inclusion or exclusion of the region.

Balanced Panel. Since our dataset is an unbalanced panel, we checked whether using 381 only countries with complete observations for the period under consideration (1961-2017) 382 will alter our results significantly. Re-estimating equation (1) with a balanced panel 383 dataset produces broadly similar estimates to the baseline results as shown in Row 8. 384 Although, there is a marginal drop in the size of the estimates for temperature effect, 385 which is not unexpected since some observations (8% of the original data points) were lost 386 in the process of balancing the panel data. The effect of precipitation changes, however, 387 remains very stable. Table 8 in the Appendix show similar results using various cutoffs 388 to generate our balanced panel data. 389

Summarily, the results from the various sensitivity tests show that our baseline estimates that measures the impact of annual weather fluctuations on beef production are robust. Therefore, large deviations from the main estimates are unexpected.

³⁹³ 4.3 Investigating Channels

Here, we investigate a potential source of mechanism that explains how weather changes affect global beef production. As discussed in the second section of this paper, there are several channels through which weather shocks can influence animal production. While a thorough investigation into these mechanisms is important, it is beyond the scope of this work. Here, we focus on how weather changes affect beef production vis-à-vis its impact on crop production.

400 4.3.1 Crop Production

Weather fluctuations may influence beef output if they affect crop production *via* changes in the quantity and quality of feed available for cattle. Previous studies (e.g., Aragón et al. 2021, Rosenzweig & Wolpin 1993) provide evidence that shortage of crop output could reduce livestock holding as a means of adaptation. Also, crop failure due to adverse weather conditions can lead to conflict between farmers and herders, leading to loss of lives and livestock (Harari & Ferrara 2018, Turner 2004). Thus, we examine the impact of temperature and precipitation on crop outputs.

Table 4 shows the impact of temperature and precipitation changes on two indices of crop production - cereal yields (ton/ha) and cereal production (kg). Dataset for both variables is from the FAO.

As expected, there is a negative impact of temperature on both yields and cereals production, although this impact is more substantial in hot countries. Specifically, a 1°C increase in temperature is associated with a 3.7% drop in cereal yields. The impact is about 3.4 percentage points higher in tropical countries. The same trend is observable in the relationship between temperature shock and cereal output. On aggregate, a 1°C higher temperature is associated with a 7.6% drop in global cereal production. The impact is greater in hot, poor, and agriculture-dependent countries. These results corroborate similar findings from Lobell et al. (2011), who report a 3.8-5.5% global net loss of maize and wheat from a marginal rise in temperature.

Table 4 also shows the usual positive relationship between precipitation changes and crop outcomes. A marginal increase in annual rainfall is associated with a 1.5% increase in global cereal yield. This impact is larger in tropical countries where a similar increase in annual precipitation will result in a 2.8% rise in global cereal yields. While the impacts in poor and agriculture-depend countries are larger than the aggregate effect, they are less than the impact in tropical countries. The same trend, but with larger coefficients, exists cereal production is used as the outcome variable.

The impacts on cereal output could also serve to explain why and how weather affects 427 beef production. For example, as higher temperatures harm crop output, the associated 428 drop in output is passed onto beef production since cattle feed on cereals. This reduction 429 in food could affect the quantity (via deaths or low reproduction rates) and quality (via 430 poor health or high feed conversion ratio (FCR)) of herds. Another pass-on effect could 431 be that as weather shocks affect crop output, farmers may substitute holding livestock 432 for farm crops as an adaptation strategy, thus reducing beef production capacity. While 433 there is evidence of how crop changes drive livestock holdings as evidenced in Aragón 434 et al. (2021), Rosenzweig & Wolpin (1993), it is not impossible to conceive of situations 435 where livestock changes affect crop output. The investigation of such potential reversed 436 causality is worth investigating. 437

Like every econometric model, there are caveats that worth mentioning regarding 438 our model. Our model does not account for possible adaptation to climate change that 439 may occur in the long run, ergo our estimates should be seen as the upper-bound of 440 possible outcomes. On the other hand, not using seasonal weather measures also makes 441 our estimates overly optimistic as we do not account for seasons that are germane to crop 442 production, an important determinant of cattle growth and development. Furthermore, 443 we do not account for the beneficial effect of CO2 on crop fertilization which may also 444 lower the indirect impact of weather changes on beef production via its beneficial effect on 445 crop production. Notwithstanding the caveats, the results are very informative for policy 446 making and complement the growing literature that seeks to understand how climate 447 change affects livestock production. 448

Table 5: Predicted Climate Change Effect on Beef Production (in logs)

Notes: The entries in the table are log changes from ACCESS-ESM1.5 for mid-term climate change (Panel A) and long-run climate change (Panel B) under SSP3-7.0 scenario. Changes are relative to a 1981 - 2010 baseline.

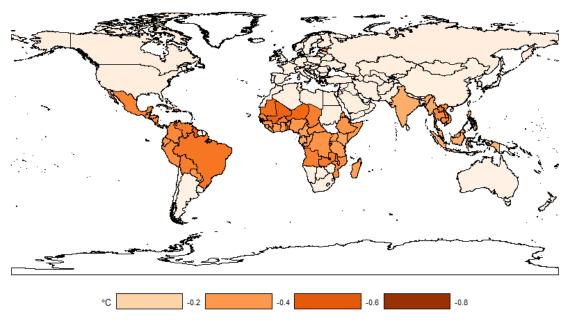

⁴⁴⁹ 5 Climate Change Projection

The last exercise is to consider the impact of projected climate change on global beef 450 production in the mid-future (2041-2060) and by the end of the century (2081-2100). 451 To carry out this task, we combine the regression estimates from the baseline model 452 with forecasted climatic changes derived from a global climate model (GCM), ACCESS-453 ESM1.5.²⁰ We calculate the change in meteorological variables at different future periods 454 by differencing the GCM's projected average weather measures over the mid-term and 455 long-term periods for each grid cell over a historical period (1981 - 2010). The importance 456 of such downscaling is to eliminate bias emanating from the GCM's current climate in 457 some locations, since observed data and GCM's historical data for the same period may 458 have different observations (see, Burke et al. (2015), Auffhammer et al. (2013) for more 459 on this issue). We recognize that averaging the GCMs tends to smooth out heterogeneous 460 spatial patterns. 461

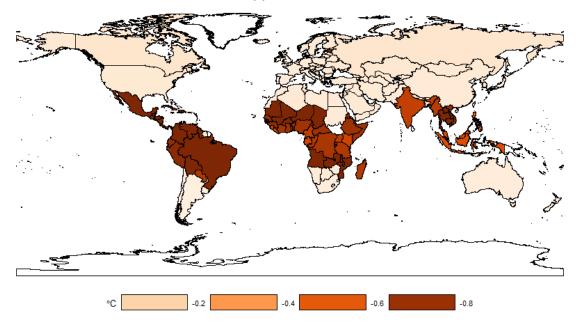

Table 5 reports the predicted log changes in global beef production under the ACCESS-462 ESM1.5 mid-term and long-run periods. The predicted loss in global beef production due 463 to climate change in 2060 ranges from 11% (in temperate regions) to 36% (in tropical 464 areas). The main agent of predicted loss is future temperature and rainfall changes in 465 the tropical and temperate regions, respectively. Additionally, Table 5 shows that the 466 effect of projected warming dominates that of rainfall changes by the end of the century. 467 Also, the predicted impact of future rainfall changes on beef production is positive in 468 the tropics while it is negative in the temperate regions. These heterogeneous impacts 469 attest to the non-uniformity of future rainfall trends, as seen in Figures 3 and 4 in the 470

²⁰Kindly refer to section 3 of this paper for a detailed description of the ACCESS-ESM1.5 GCM.

(a) 2081 - 2100

Notes: The maps represent aggregate (temperature + precipitation) impacts (as log changes) from ACCESS-ESM1.5 for (a) mid-term climate change and (b) long-run climate change under SSP3-7.0 scenario. Changes are relative to a 1981 - 2010 baseline.

Figure 1: Spatial Distribution of Predicted Climate Change Aggregate Impact on Beef Production (in logs) Appendix. Figure 1 displays the spatial distribution of the cumulative impact of climate
change under the mid-term and long-term scenarios. Important information from Figure 1 is that the overall adverse effect of climate change on beef production is almost
completely centered in tropical countries.

An important observation worth noting is that the effect of global warming stochastically dominates that of rainfall changes. A reason for this is that while every part of the world will experience warming, though unequally, there is no unanimity on the future trend of rainfall, as seen from Figures 3 and 4 in the Appendix. It is significant to note that one key assumption in the use of climate models for future predictions is the *ceteris paribus* assumption, as well as the belief that climate will continue to affect livestock production in the future.

482 6 Conclusion

This paper measures the impact of weather fluctuations on global livestock produc-483 tion using panel data from 1961 to 2017. In contrast to the integrated assessment and 484 Ricardian models, the method employed in this paper exploits the exogeneity of cross-485 time variations in weather to identify the causal effects of temperature and precipitation 486 on livestock production. The results show that, at the global level, a 1°C increase in 487 temperature will lead to a 9.7% reduction in beef production on average, with most of 488 this effect centered in tropical countries. Poorer countries would also experience a 27%489 reduction as opposed to 4% in countries with higher income levels. On the other hand, an 490 additional mm increase in annual precipitation would lead to a 2.1% increase in produc-491 tion in tropical countries but a 1.9% decrease in temperate ones. We also find that beef 492 production in agriculture-dependent countries is more affected by warming than in non-493 agricultural economies. Overall, poor and agricultural-dependent countries located in the 494 tropics are severely affected by warming, notwithstanding the positive effect of rainfall 495 changes in such regions. The projections indicate that the effects of climate change by 496 2070 would range from 11% in temperate regions to 36% in tropical areas, with global 497 warming playing a more significant role in determining livestock output than predicted 498 changes in rainfall patterns in the longer term. 499

An important message from this study is that climate change affects livestock produc-500 tion and, consequently, food security, which will be even more important in the future. 501 Global production of livestock and livestock products will be negatively impacted (due 502 to diseases, water availability, etc.), especially in poor and tropical regions. Therefore, 503 mitigation and adaptation policies are important to protect the sustainability of livestock 504 production, especially in these vulnerable regions. Some ways that agricultural systems 505 could adapt to the changing climate include adopting new and improved strategies for 506 animal breeding, changing farmers' perception, and the overall incorporation of advances 507

in science and technology, including the improvement of animal nutrition and genetics. GIS and remote sensing technologies could also be adopted to optimize the timing, location, and patterns of grazing. But all of these adaptations would be inadequate if not supported at the policy-making level with appropriate policy frameworks to enhance their effects. For example, the inclusion of farmers in the decision-making process is critical to the understanding of the issues confronting their activities and the success of any mitigating policies.

Some limitations to the study are as follow. The panel data method do not account for 515 inter-annual tradeoffs farmers make that may be affecting the contemporaneous estimates 516 presented in the paper. Consequent to this methodological shortcoming, this study is 517 picking up short-run changes in inventory in the cattle herd that may not be indicative 518 of long run changes associated with climate change.²¹ Besides, the panel data model 519 does not account for adaptation to gradual changes in climate. We expect farmers to 520 take adaptive measures (such as migrating animals to cool areas) in the face of climate 521 change. Accounting for such adaptive techniques would dampen the damage estimate 522 from our model. 523

As with other empirical models, real-world agricultural processes are more complex than what models represent. There is tremendous heterogeneity in several channels through which climate change affects animals productivity. It is practically difficult for any single model to answer all the questions, prove all channels, or account for all uncertainties. Therefore, this paper contributes to the climate econometrics and agricultural economics literature that applies econometric techniques to understand the interaction between weather factors and livestock production.

Table 7: Alternative Weather Dataset

V country is defined as tropical if its median temperature is above the global median; otherwise, it is temperate. A country is rich iff it is higher income or upper-middle income by World Bank classification, else it is poor. A country is agriculture-dependent if it has above median share of GDP in agriculture in 2000. Temperature is in degrees Celsius and precipitation is in mm units per year. Sample period is **Significant at the 1 percent level. *Significant at the 5 percent level. *Significant at the 10 percent level.

Table 8:

if its median temperature is above the global median, "poor" if it is classed as a lower income or lower-middle income by World Bank classification, "agriculture-dependent" if it has above median share of GDP in agriculture in 2000. Temperature is in degrees Celsius and precipitation is in mm units per year. Sample period is 1961 - 2017 for all specifications. ***Significant at the 1 percent level. **Significant at the 1 percent level.
